Received 2 June 2005; revised 31 October 2005; accepted 23 November 2005; published 22 February 2006.

[1] Characteristic vegetation and biofuels in major ecosystems of southern Africa were sampled during summer and autumn 2000 and burned under semicontrolled conditions. Elemental compositions of fuels and ash and emissions of CO<sub>2</sub>, CO, CH<sub>3</sub>COOH, HCOOH, NO<sub>X</sub>, NH<sub>3</sub>, HONO, HNO<sub>3</sub>, HCl, total volatile inorganic Cl and Br, SO<sub>2</sub> and particulate C, N, and major ions were measured. Modified combustion efficiencies (MCEs, median = 0.94) were similar to those of ambient fires. Elemental emissions factors  $(EF_{el})$  for CH<sub>3</sub>COOH were inversely correlated with MCEs; EF<sub>el</sub>s for heading and mixed grass fires were higher than those for backing fires of comparable MCEs. NO<sub>X</sub>, NH<sub>3</sub>, HONO, and particulate N accounted for a median of 22% of emitted N; HNO<sub>3</sub> emissions were insignificant. Grass fires with the highest  $EF_{el}s$  for NH<sub>3</sub> corresponded to MCEs in the range of 0.93; grass fires with higher and low MCEs exhibited lower EF<sub>el</sub>s. NH<sub>3</sub> emissions for most fuels were poorly correlated with fuel N. Most Cl and Br in fuel was emitted during combustion (median for each = 73%). Inorganic gases and particulate ions accounted for medians of 53% and 30% of emitted Cl and Br, respectively. About half of volatile inorganic Cl was HCl indicating significant emissions of other gaseous inorganic Cl species. Most fuel S (median = 76%) was emitted during combustion; SO<sub>2</sub> and particulate  $SO_4^{2-}$  accounted for about half the flux. Mobilization of P by fire (median emission = 82%) implies large nutrient losses from burned regions and potentially important exogenous sources of fertilization for downwind ecosystems.

## 1. Introduction

[2] Biomass burning is a major source for atmospheric pollutants [e.g., *Crutzen et al.*, 1979; *Crutzen and Andreae*, 1990; *Andreae and Merlet*, 2001]. The amount of carbon emitted to the atmosphere from the combustion of biomass is similar to that from fossil fuels [*Crutzen and Andreae*, 1990]. Currently, Africa accounts for about 35% of biomass burning globally (J. A. Logan and R. Yevich cited by *Lobert et al.* [1999]). The most abundant compounds emitted during

biomass burning are water vapor, carbon dioxide (CO<sub>2</sub>) and carbon monoxide (CO). However, thousands other gaseous and particulate species have been detected in exhaust plumes [e.g., *Johnson and Plimmer*, 1959] with significant implications for atmospheric and biogeochemical cycles. In addition, chemical reactions rapidly (<1 hour) transform the compositions of fresh plumes [e.g., *Trentmann et al.*, 2005]; consequently, quantification of primary biomass-burning emissions is essential for resolving the chemical evolution of plumes and predicting associated environmental influences. Despite intense scientific study over the past three decades, however, global and regional emissions of many compounds are still poorly constrained.

[3] Emissions from open burning are controlled by a small number of highly variable factors including fuel moisture, physical size and arrangement of the fuel, and wind conditions. These factors regulate overall burning efficiency (e.g., the ratio of CO<sub>2</sub> emitted to total C emitted [e.g., *Lobert and Warnatz*, 1993]). Thus, as burning efficiency decreases, emissions of CO and organic C-containing compounds increase relative to CO<sub>2</sub>. The elemental contents of biomass also influence corresponding emissions of N- [*Hao et al.*, 1991; *Lobert et al.*, 1991], S- [*Delmas*, 1982; *Bingemer et al.*, 1991], and halogen-containing compounds [e.g., *Rasmussen et al.*, 1980; *Andreae et al.*, 1996;

*Blake et al.*, 1996; *Lobert et al.*, 1999]. Most N and S in biomass is associated with organic constituents whereas halogens exist primarily as electrolytes. During high-temperature combustion, these species often form reactive, short-lived intermediates that are emitted directly or recombine with carbon-containing fragments or hydrogen atoms to form more stable secondary products that are subsequently emitted [*Lobert and Warnatz*, 1993].

[4] Available evidence indicates that biomass-burning emissions represent major fluxes in regional or global budgets of nitrogen [e.g., *Lobert et al.*, 1991], sulfur [e.g., *Bingemer et al.*, 1991], chlorine [e.g., *Lobert et al.*, 1999], bromine, and iodine [*Andreae et al.*, 1996; *Blake et al.*, 1996; *Ferek et al.*, 1998]. Relative to those of C, however, our knowledge of speciated emissions of N-, S-, and halogencontaining compounds from different types of biomass burning is limited and, consequently, regional and global flux estimates are considerably more uncertain. In particular, the general lack of coupled data for the elemental composition of fuels and the corresponding speciated emissions during combustion seriously constrains current predictive capabilities [e.g., *Lobert et al.*, 1999].

[5] Under the auspices of the Southern Africa Regional Science Initiative during austral winter 2000 (SAFARI 2000), biomass-burning emissions were investigated in the savanna and Miombo ecosystems of Southern Africa [*Swap* et al., 2003]. Multiple integrated approaches including semicontrolled experimental burns, prescribed burns, ambient burns of opportunity, measurements at surface sites and from aircraft, satellite imagery, and model calculations were employed to characterize the burned area, quantify local and regional fluxes, and evaluate environmental implications. In this paper, we report emission fluxes of CO<sub>2</sub>, CO, NO<sub>X</sub> (NO + NO<sub>2</sub>) soluble reactive trace gases (CH<sub>3</sub>COOH, HCOOH, NH<sub>3</sub>, HONO, HNO<sub>3</sub>, HCl, SO<sub>2</sub>), total volatile inorganic Cl and Br, and particulate species (total C, CH<sub>3</sub>COO<sup>-</sup>, HCOO<sup>-</sup>, (COO)<sup>2</sup><sub>2</sub><sup>-</sup>, total N, NH<sup>4</sup><sub>4</sub>, NO<sup>-</sup><sub>3</sub>, Cl<sup>-</sup>,

 $Br^-$ ,  $SO_4^{2-}$ ,  $PO_4^{2-}$ ,  $K^+$ ,  $Ca^{2+}$ ,  $Na^+$ , and  $Mg^{2+}$ ) as functions of fuel composition and combustion conditions during 48 semicontrolled experimental burns of representative biomass types from the major ecosystems of southern Africa and of cow dung from India. Individual data for all experimental burns together with images of the sampling sites, fuels, and fires and related ancillary data are available for further evaluation through the project web site at http:// science.jurgenlobert.net/.

# 2. Methods

# 2.1. Biomass Collection and Processing

[6] During August through October, 2000, characteristic vegetation and biofuels including grasses, shrubs, branches, litter, agricultural waste (maize stalks), and locally produced charcoal were sampled at multiple sites within the savanna grasslands of Etosha National Park, Namibia (ENP) and Kruger National Park, South Africa, (KNP); in the Miombo woodlands of Malawi (MAL); and in the Miombo dambos (grasslands) in the Zambezi River valley west of Mongu, Zambia (ZAM) (Figure 1 and Table 1). Fuels were collected by or in consultation with collaborating park rangers and scientists who worked in each region and were knowledgeable about local burning practices and conditions. Typically, 3 to 5 kg (wet weight) of major grasses and leafy material and 6 to 9 kg of branches were sampled at any given site. Fresh vegetation was weighed, air dried for 2 to 4 days, and reweighed on location; loosely packed in polyethylene-lined cardboard boxes; and express shipped to the Max Planck Institute (MPI) in Mainz, Germany. The packing procedure represented a compromise between the competing needs to minimize potential alteration of fuel composition during shipment via microbial activity versus contamination. The interior liners were left open to air exchange, which allowed samples to equilibrate with variations in temperature and relative humidity during shipment and thereby minimize microbial and fungal growth and associated alteration of chemical composition. The edges of the boxes were sealed with polyethylene tape, which minimized direct air exchange and associated contamination. Inspection upon receipt revealed no obvious signs of biological deterioration or contamination of samples. Samples were stored in an environmental chamber at ambient temperature and humidity until burned. Cow dung that had been sampled previously in India (IND) and similarly processed was also analyzed as part of this study.

# 2.2. Experimental Burns and Exhaust Sampling

[7] Between 11 November 2000 and 16 January 2001, biomass samples were reweighed at MPI; most were rehydrated to near ambient water contents by spraying with a fine mist of >18 M $\Omega$  cm<sup>-1</sup> deionized water (DIW) and incubating in sealed plastic bags for 1 to 2 days prior to combustion (Table 1). Samples were subsequently weighed and burned under semicontrolled conditions at the MPI burn facility; fresh exhaust for chemical analysis was sampled from the stack (approximately 2 m above the burn table) (see *Lobert et al.* [1990, 1991] for detailed description of the facility). Ambient air was similarly characterized. Fuel and residual ash were subsampled and analyzed for elemental constituents. In addition to the species described in more

detail below, collaborating investigators analyzed the exhaust for CH<sub>4</sub> and N<sub>2</sub>O with gas chromatography (GC), methyl halides with GC mass spectrometry (GC-MS), SO<sub>2</sub> and volatile organics with atmospheric pressure chemical ionization (AP) MS [Jost, 2002], volatile organics with proton transfer reaction (PTR) MS, and speciated particulate organic and elemental carbon. Hg was also measured in a subset of paired fuel and ash samples [Friedli et al., 2003]. Wet weight of fuels burned during individual fires ranged from about 0.5 to 0.7 kg for grasses to about 2 kg for branches. Fire durations ranged from about 5 min for dryer savanna grasses to several hours for larger branches, charcoal, and dung; typically, two experimental burns were conducted each day. Combustion temperature, emitted biomass (via weight loss), and the mass flux of exhaust through the stack were monitored continuously during each experiment. The angle of the burn table and the initial ignition point of the fire were varied to simulate a range of different burn conditions (Table 1). Three basic fire types were evaluated. Backing fires were ignited on the downwind (top) elevation of the table, heading fires were ignited on the upwind (bottom) elevation of the table, and mixed fires that include both backing and heading components were ignited in the center or on the side. To qualitatively evaluate the influence of regional stoves on emission fluxes from the combustion of charcoal and dung, a small brick oven was assembled on the burn table for some experiments and preheated prior to igniting the fuel.

## 2.3. Elemental Contents of Biomass and Ash

[8] At MPI, representative air-dried subsamples of biomass and fresh subsamples of ash were milled to pass through a 1 mm screen and then through a 0.08 mm screen yielding a mean particle size of about 60 µm [Lobert, 1989]. Samples were then weighed, dried at 72°C for 48 hours [e.g., McKenzie et al., 1996] cooled in a desiccator, reweighed, stored in sealed glass containers, and transported to the University of Virginia (UVA) for analysis. At UVA, subsamples of approximately 100 mg each were analyzed in triplicate for C and N on a Thermoquest CE (Carlo Erba) Model NA Elemental Analyzer. The instrument was calibrated with atropine (C = 70.6%; N = 9.39%) at the beginning and end of each analytical run. Methionine (C = 40.3%; N = 9.39%), atropine, and blanks were analyzed as unknowns between each set of approximately 10 samples. Results indicate that the data are unbiased. Average analytical detection limits (DLs; defined here as twice the average standard deviation for replicate sets of analyses of samples) for biomass were 0.0056 kg C kg $_{dry wt}^{-1}$  and 0.28 g N kg $_{dry wt}^{-1}$  and for ash were 0.0054 kg C kg $_{dry wt}^{-1}$  and 0.13 g N kg<sub>dry wt</sub>.

[9] One gram of each sample was oxidized at 25 atm  $O_2$ in a Parr bomb containing 10 mL of 5 mN Li<sub>2</sub>CO<sub>3</sub> and extracted with deionized water to a final volume of approximately 50 ml. The Parr bomb was blanked with benzoic acid. H<sub>2</sub>O<sub>2</sub> was added to extracts prior to analyzing SO<sub>4</sub><sup>2-</sup> and PO<sub>4</sub><sup>3-</sup> and H<sub>4</sub>N<sub>2</sub> was added prior to analyzing SO<sub>4</sub><sup>2-</sup> [e.g., *Smith et al.*, 1977; *Butler et al.*, 1979; *Rubin*, 1987]. Extracts were subsequently analyzed for the above anions and for base cations (K<sup>+</sup>, Ca<sup>2+</sup>, Na<sup>+</sup> and Mg<sup>2+</sup>) by ion chromatography (IC) on a Dionex 4000 series instrument. Performance was verified by analysis of standard additions

and audit solutions traceable to the National Institute of Standards and Technology. Average DLs (estimated as twice the average standard deviation for replicate analyses of low-concentration standard solutions) for S, P, Cl, Br, and I content of biomass were 9.1, 6.6, 21, 4.3, and 30 mg kgdry  $_{\rm wt}^{-1}$ , respectively, and those of ash were 2.4, 5.1, 33, 2.2, and 39 mg kg $_{\rm dry}^{-1}$  wt, respectively. The I contents of all samples were below the DL. Average DLs for K, Ca, Na and Mg in biomass and ash were 74, 2.5, 13, and 15 mg  $kg_{dry wt}^{-1}$ , respectively. Replicates and splits were routinely processed and analyzed. Data for field replicates (paired subsamples of biomass that were processed independently, N = 3), field splits (paired subsamples of biomass that were partitioned after grinding and subsequently processed independently; N = 5), and lab splits of biomass (N = 6) and ash (N = 7) were averaged for evaluation of associated emissions from individual fires.

# 2.4. $CO_2$ , CO, and $NO_X$

[10] Subsamples of exhaust streams for analysis of  $CO_2$ and CO were continuously pumped through a cold trap  $(-20^{\circ}C)$ , a glass fiber filter (Alltech) and a stainless steel sinter filter (Valco). Streams were then split and dynamically diluted into the analytical ranges of the instrument. Sampling rates were regulated with mass flow controllers. Both gases were quantified using two nondispersive infrared analyzers (model BINOS, Heraeus) each of which operated at two different concentration ranges. The  $CO_2$ instrument contained two separate cells with ranges of 0-1500 ppmv and 0-6 Vol-%, respectively; the CO instrument contained a single cell that was electronically split into ranges of 0-100 ppmv and 0-2000 ppmv. The DL for both instruments was about 5 ppmv.

[11] Subsamples of the exhaust stream for analysis of NO<sub>X</sub> (NO + NO<sub>2</sub>) were continuously pumped through a heated, 6.3 mm OD by 8-m long Teflon tube followed by a Teflon filter (0.5  $\mu$ m, Supelco) and a cold trap (-20°C). NO<sub>X</sub> was quantified by chemiluminescence using a Thermo Electron Model 14A analyzer equipped with a stainless steel converter maintained at 600°C to minimize interference by acetonitrile and other nitrogen-containing compounds [*Lobert et al.*, 1991]. The detection limit was about 50 ppbv. All three instruments were routinely calibrated with commercial standard gas mixtures (Steininger) in the measured concentration ranges.

## 2.5. Water-Soluble Reactive Trace Gases

[12] Soluble carbon- (CH<sub>3</sub>COOH, HCOOH), nitrogen-(NH<sub>3</sub>, HONO, HNO<sub>3</sub>), chlorine- (primarily HCl), and sulfur- (SO<sub>2</sub>) containing gases in the exhaust were sampled at a nominal rate of 20 L min<sup>-1</sup> with tandem mist chambers (MCs) each of which contained 20 mL of DIW [e.g., *Russell et al.*, 2003; *Keene et al.*, 2004]. All air volumes reported herein were measured with mass flowmeters normalized to 0°C and 1 atm. Sample exhaust was pulled through a 47 mm quartz filter (Pallflex QAT-UP 2500) mounted in a stainless steel housing attached to the stack followed by an insulated 4.76 mm ID by 1.5-m long Teflon tube and a 47 mm Teflon filter (Gelman, 2  $\mu$ m pore size) before entering the first chamber. The residence time of sample air in the inlet was approximately 0.1 second. Evaporative losses of mist solutions were manually replaced during

operation to minimize variability in collection efficiencies [e.g., Keene et al., 1993]. Dissolved ions in exposed mist solutions were measured on site (generally within a few hours after recovery) by IC using Dionex 4000 series instruments. Testing during the initial stages of the experiment revealed significant condensation of analytes, water, and other species on the walls of the insulated Teflon inlet and the Teflon filter. Consequently, condensed analytes upstream of the first mist chamber were quantitatively (>95%) extracted by flushing exposed surfaces of the tube, filter, and housing with two sequential 5 mL DIW rinses. These rinses were subsequently analyzed and included in the calculation of concentrations in the exhaust; associated analytical uncertainties were also incorporated in estimating overall precisions and detection limits (reported below). Median recoveries of CH<sub>3</sub>COOH, HCOOH, NH<sub>3</sub>, HONO, HCl, and SO<sub>2</sub> from the inlet corresponded to 21%, 25%, 28%, 3%, >98%, and 16%, respectively, of total concentrations. It is evident that reliable measurement of such rapidly condensing gases in fresh biomass-burning exhaust requires quantitative extraction and analysis of exposed surfaces upstream of sampling media or detectors. Dynamic blanks were collected prior to each sample by loading chambers with DIW and pulling clean air [Keene et al., 1993] through the system for approximately 10 seconds. Thereafter blanks were processed using the same procedures as samples. Ambient air was sampled over 1-hour intervals prior to the first experimental burn each day and characterized for soluble trace gases (and for volatile inorganic halogens and particulate species, described below) using similar procedures.

[13] Performance characteristics of the standard MC-IC technique for most of these compounds in ambient air have been critically evaluated [see Keene et al., 2004, and references therein]; those for HONO are discussed below. Collection efficiencies for all species in ambient air are greater than 95%. To our knowledge, however, performance of this approach when sampling fresh biomass-burning emissions have not been critically evaluated previously. Comparison of measured concentrations of analytes in the upstream and downstream mist solutions indicated somewhat lower collection efficiencies for some analytes in biomass-burning emissions relative to ambient air. On the basis of the assumption that a given compound was sampled with equal efficiency in both tandem chambers, the collection efficiencies and original mixing ratios in the burn exhaust were calculated directly. Median collection efficiencies for the tandem system ranged from a low of 74% for  $SO_2$  to a high of >98% for NH<sub>3</sub> and HCl.

[14] Fresh mist solutions that were analyzed immediately after recovery contained significant concentrations of  $NO_2^-$ (presumably from HONO dissolution) but virtually no  $NO_3^-$ (from HNO<sub>3</sub> dissolution). However, sequential, time series analyses of stored samples revealed that  $NO_2^-$  was quantitatively oxidized to  $NO_3^-$  over periods of 5 to 48 hours. We infer that HONO was the primary source for both  $NO_2^-$  and  $NO_3^-$  in mist solutions and that HNO<sub>3</sub> was produced by secondary reactions. Reported fluxes of HONO correspond to the measured sum of  $NO_2^-$  plus  $NO_3^-$  in exposed mist solutions and inlet flushes. Performance characteristics of the MC-IC technique for HONO have not been rigorously characterized. However, HONO in polluted coastal air at

Appledore Island, MA, USA (43.0°N, 70.6°W) during July 2004 was measured in parallel by both MC-IC and longpath differential optical absorption spectroscopy (DOAS) with a path length of 4.6 km [Stutz et al., 2002; J. Stutz, University of California, Los Angeles, unpublished data, 2005]. The mist chamber samplers were deployed on a tower ( $\sim$ 43 m asl) and configured and operated using established procedures [e.g., Keene et al., 2004]; the DOAS telescope and spectrophotometer were positioned approximately 8 m below. Individual DOAS measurements were averaged over each MC sampling interval. A reduced major axis regression (RMA [Hirsch and Gilroy, 1984]) of all paired MC-IC (Y axis) versus DOAS (X axis) data yielded a significant linear correlation (slope = 1.2, intercept = 49,  $r^2 = 0.57$ , N = 22, range <45 to 730 pptv); the slope and intercept were not significantly different from 1 and 0, respectively. About half of the DOAS observations were below DLs and thereby constrained resolution of the intercomparison. Although these results indicate reasonable agreement with an established technique, fluxes reported herein are considered semiquantitative (because of limited testing) and upper limits (based on published evidence that HONO may be produced via artifact reactions [e.g., Zhou et al., 2002]).

[15] Average DLs for  $NH_3$ , HONO,  $CH_3COOH$ , HCOOH, HCl, and  $SO_2$  in burn exhaust were 0.80, 6.2, 47, 5.6, 3.2, and 1.2 ppbv, respectively. The average mixing ratios of all analytes in ambient air were less than 0.5% of those in fire emissions and, consequently, were ignored in calculating fluxes.

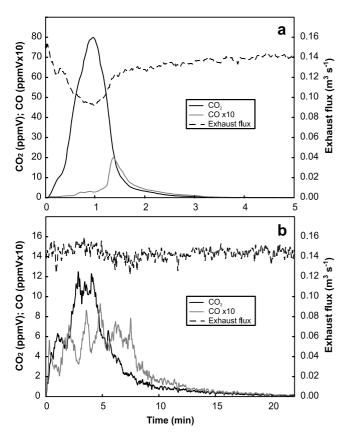

#### 2.6. Volatile Inorganic Halogens

[16] Volatile, inorganic Cl, Br, and I in burn exhaust were sampled at an average flow rate of 95 L min<sup>-1</sup> immediately downstream of the stack using a filter pack [e.g., *Li et al.*, 1994; *Pszenny et al.*, 2004, and references therein]. Particles were removed by drawing sample air through a 142-mm-diameter quartz fiber filter (Pallflex QAT-UP 2500) mounted in a stainless steel housing attached to the stack and gases were sampled quantitatively downstream on tandem 90 mm Rayon filters (Schleicher and Schuell 8S) impregnated with 10% K<sub>2</sub>CO<sub>3</sub> -10% glycerol and mounted in a Delrin housing. Flow was measured with a mass flowmeter.

[17] Exposed quartz fiber and impregnated rayon filters were transferred to sealed polyethylene bags, placed in airtight Mason jars to prevent gas exchange, and stored frozen until analysis. At UVA, entire impregnated filters were extracted under sonication in 20 mL DIW and analyzed for halogen ions by IC. Average DLs for volatile inorganic Cl and Br in the burn exhaust were 2.0 and 0.4 ppbv, respectively; volatile I was undetectable. Analysis of tandem filters indicated collection efficiencies greater than 97% for both Cl and Br gases.

# 2.7. Particulate Species

[18] In a clean bench at UVA, two or three strips (approximately  $6 \times 67$  mm each) were cut from exposed portions of the quartz filters described above, measured and independently analyzed for total particulate C and N on a Thermoquest CE (Carlo Erba) Model NA Elemental Analyzer. Calibration procedures were similar to those de-

**Figure 2.** Molar mixing ratios of  $CO_2$  (solid line) and CO (shaded line) and the mass flux of exhaust through the stack normalized to standard temperature (0°C) and pressure (1 atm) (dashed line) during typical experimental burns of (a) grass (Kruger sample 13) and (b) shrubs (Etosha sample 7).

scribed for biomass and ash samples and average detection limits were 0.25 mmol C m<sup>-3</sup> and 8.4 µmol N m<sup>-3</sup>. Half sections of each quartz filter were extracted under sonication in DIW and analyzed for soluble ionic constituents [including total (dissociated + undissociated) NH<sup>+</sup><sub>4</sub>, NO<sup>-</sup><sub>3</sub>, CH<sub>3</sub>COO<sup>-</sup>, HCOO<sup>-</sup>, (COO)<sup>-2</sup>, Cl<sup>-</sup>, Br<sup>-</sup>, SO<sup>2</sup><sub>4</sub><sup>-</sup>, PO<sup>3</sup><sub>4</sub><sup>-</sup>, K<sup>+</sup>, Ca<sup>2+</sup>, Na<sup>+</sup>, and Mg<sup>2+</sup>] by IC. Corresponding DLs were <0.001, 0.038, 0.15, 0.028, <0.001, 0.075, 0.013, 0.017, 0.030, 0.037, 0.058, 0.18, and 0.046 µmol m<sup>-3</sup>, respectively.

# 2.8. Measurement Uncertainties

[19] In addition to random analytical errors summarized above, two other important sources of uncertainty constrain interpretation of results reported herein. A detailed evaluation of chemical variability within components of individual biomass samples (e.g., seeds, leaves, and stems of a given grass sample) was beyond the scope of this study. The representativeness of biomass subsampled for chemical analysis and for experimental burns was based on visual inspection. Elemental data for paired field replicates of grass samples generally agreed within  $\pm 15\%$  suggesting that subsamples of such fairly homogeneous fuels were representative. The consistency in percentage emissions of elemental constituents from paired independent burns of separate subsamples of the same fuels (Table 1) also indicate that subsampling was generally representative. However, some elemental components (including P, Br, and base cations) of paired subsamples of Indian dung varied by greater than a factor of two. On the basis of these results, we infer that nonrepresentative subsampling contributed to divergence in emissions of some analytes during independent burns of dung (Table 1). Data for other more heterogeneous fuel types may be similarly impacted. We return to this issue below.

[20] With the exception of  $CO_2$ , CO, and  $NO_X$ , data reported herein correspond to integrated samples collected at near-constant rates over entire durations of individual fires. Because the density of the exhaust varied as a function of temperature, the mass flux of exhaust through the stack varied (typically by about 5% to 40%) during most burns (e.g., Figure 2). Some compounds (e.g.,  $CO_2$ ) are emitted preferentially under hotter, flaming conditions whereas others (e.g., CO) are emitted preferentially under cooler, smoldering conditions. Consequently, concentrations and associated emission fluxes of individual compounds did not always vary in direct proportion with the mass flux of burn exhaust. To evaluate the corresponding potential magnitude of error in emission fluxes estimated from integrated samples, we calculated and compared the integrated emission fluxes of CO<sub>2</sub> and CO depicted in Figure 2 using two different approaches: (1) The individual paired measurements of concentrations and mass fluxes during the course of each burn and (2) the average concentration of each compound in the exhaust and the corresponding total mass flux through the stack over the entire burn. The latter approach is analogous to estimating fluxes on the basis of integrated samples collected at constant rates. Relative to those based on the individual paired measurements, the emission fluxes of  $CO_2$  and  $C\bar{O}$  calculated from average concentrations over the durations of the burns were 24% and 6% higher, respectively, for the grass fire and 2% lower and <1% higher, respectively, for the shrub fire. Comparisons based on data from other experimental burns yielded similar results. These comparisons suggest that integrated sampling for compounds emitted primarily during the flaming stage of high-temperature grass fires overestimated emission fluxes by 15% to 25%. For lower-temperature fires and for compounds emitted primarily under smoldering conditions, integrated sampling yielded representative emission fluxes. Given the relatively large accumulated uncertainties in quantifying biomass-burning emissions, our analysis will focus primarily on sample statistics for central tendencies including median values and the middle 50th (i.e., 25th through 75th) percentile of results.

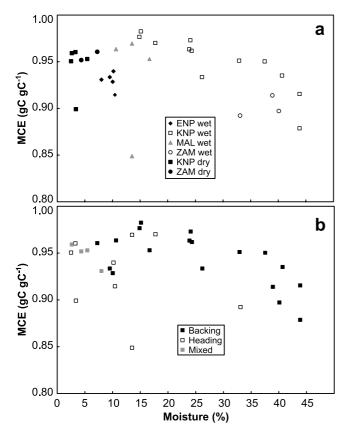

#### 2.9. Calculations

[21] Emission fluxes are reported using three common conventions.

[22] 1. The standard emission factor  $(EF_{st})$  for species (x) is defined as

$$EF_{st-X} = \frac{M_X}{M_{biomass}}$$

where  $M_X$  is the integrated mass (molecular, ionic, or elemental) in grams of species X measured in the exhaust

**Figure 3.** MCE versus moisture content for experimental burns of grass as functions of (a) region and rehydration and (b) type of burn.

over the course of a fire and  $M_{biomass}$  is the corresponding mass in kilograms dry weight of biomass that is burned and emitted (i.e., excluding ash and any unburned fuel).

[23] 2. The elemental emission factor  $(ER_{el})$  is defined as

$$EF_{el-X} = \frac{M_{el-X}}{M_{el-biomas}}$$

where  $M_{el-X}$  is the integrated mass in grams of a given element associated with species X measured in the exhaust and  $M_{el-biomass}$  is the corresponding mass in kilograms of that element associated with the biomass that is burned and emitted.

[24] 3. Molar emission ratios relative to CO ( $ER_{CO}$ ) and CO<sub>2</sub> ( $ER_{CO2}$ ) are defined as (using CO as an example)

$$ER_{CO} = \frac{Mol_X}{Mol_{CO}}$$

where  $Mol_X$  is the integrated molar mixing ratio of species X measured in the exhaust and  $Mol_{CO}$  is the corresponding integrated molar mixing ratio of CO. The following analysis focuses primarily on interpretation of  $EF_{el}s$  and  $EF_{st}s$  for soluble reactive trace gases and particulate species.

[25] The modified combustion efficiency (MCE) is an important diagnostic of corresponding emission fluxes.

$$MCE = \frac{CO_2}{CO_2 + CO}$$

where all units are based on g C.

# 3. Results and Discussion

#### **3.1.** Fire Characteristics

[26] MCEs for most burns fell within a fairly narrow range (Table 1 and Figure 3). The middle 50th percentile range for all burns (0.91 to 0.95 g C g  $C^{-1}$ ) was very similar to the reported range for ambient savanna fires in southern Africa (e.g., 0.90 to 0.95 g C g  $C^{-1}$  [*Ward et al.*, 1996]). Both the moisture content of fuel and the nature of the burn (backing, heading, or mixed) influenced MCE. For the subset of experimental burns involving grasses, as moisture contents increased from about 20% to 44%, corresponding MCEs decreased from greater than 0.95 to less than 0.90 (Figure 3). Although the MCEs for some heading fires fell within the range of those for backing fires involving grasses of comparable moisture content, others were substantially lower. The four lowest MCE values for the subset of fires involving grasses with moisture contents less than 35% (N = 25) were all associated with heading fires (Figure 3b). Results also suggest regional differences in these relationships. Backing fires involving grasses from ENP were systematically lower than those of comparable moisture contents from other regions (Figure 3a). Relative to other fuels, the two processed biofuels (charcoal and dung) exhibited lower MCEs ranging from 0.81 to 0.85 g C g <sup>-1</sup>. Dung burned on an open platform and within a brick C oven yielded similar values suggesting that the lower MCEs for this biofuel (and perhaps for charcoal) were primarily a function of fuel characteristics rather than the nature of combustion. Combustion completeness [CC = (initial drywt. of biomass - the dry wt. of residual unburned biomass)/ initial dry wt. of biomass] for most fires during this investigation (Table 1) were generally higher than those for ambient fires in southern Africa (e.g., 0.87 to 0.94 [Ward et al., 1996]; 0.30 to 0.95 [Hély et al., 2003]).

# 3.2. Carbon

[27] With the exception of charcoal and cow dung, the carbon contents of fuels fell within a relatively narrow range and virtually all (median = 97%) was emitted during combustion (Table 1). On the basis of median values, CO2 and CO accounted for greater than 99% of the estimated carbon flux (Tables 2a-2d) and median EF<sub>st</sub>s for these compounds generally fell within the ranges of reported values (Table 3). On the basis of median values, total particulate C accounted for about 1% and gaseous carboxylic acids about 0.2% of the C emission flux. Particulate CH<sub>3</sub>COO<sup>-</sup>, HCOO<sup>-</sup>, and  $(COO)_2^{2-}$  typically accounted for <1% of total particulate C (Table 2). EF<sub>st</sub>s for particulate C during these experimental burns were generally within the range of values reported in the literature but those for gaseous carboxylic acids tend to be somewhat lower (Table 3). Most previously published emission factors for the carboxylic acids were based on measurements in plumes from ambient fires. Carboxylic acids are produced rapidly (<1 hour) as emissions age [Yokelson et al., 2003; Trentmann et al., 2005] and, consequently, measurements in ambient plumes reflect contributions from both primary emissions and secondary production. Relative differences in the ages of sampled plumes thereby contribute to the somewhat lower EFs for carboxylic acids measured in fresh emissions during this study. The nature of the burn also influenced EF<sub>el</sub>s for carboxylic acids. For example, during

the combustion of savanna grasses, most heading and mixed fires exhibited systematically higher  $EF_{el}s$  for  $CH_3COOH$ relative to backing fires of comparable MCEs (Figure 4). An RMA regression of  $EF_{el}$  versus MCE for heading and mixed fires (N = 10 excluding 2 outliers) yielded a slope of -64.7, an intercept of 63.7 and a r<sup>2</sup> of 0.85; the corresponding regression for backing fires (N = 16) yielded a slope of -19.3, an intercept of 19.1, and a r<sup>2</sup> or 0.24. The highest  $EF_{el}s$  for CH<sub>3</sub>COOH were associated with dung, litter, and heading burns of savanna grasses (Figure 4).

[28] The median integrated exhaust flux of carbon via all species reported herein was 101% of the corresponding emission flux of fuel C during combustion (Table 4). Although these integrated exhaust fluxes do not include minor additional contributions from other volatile organic compounds (maximum of a few percent [*Andreae and Merlet*, 2001]), the agreement between the sum of carbon-containing species measured in the exhaust and total fuel C emitted during the burns is well within the overall combined uncertainty of the associated measurements.

# 3.3. Nitrogen

[29] With the exception of dung, the N contents of fuels fell within a fairly narrow range and, like carbon, most (median = 95%) was emitted during combustion (Table 1). Grasses in Miombo ecosystems generally contained less N than those in the Kruger and Etosha savannas (Table 1), which is consistent with their relatively lower fertility [e.g.,

**Figure 4.** EF<sub>el</sub> for CH<sub>3</sub>COOH versus MCE.

*Hély et al.*, 2003]. In contrast to carbonaceous species, measured N-containing analytes in the exhaust corresponded to relatively minor fractions (median = 22%) of the emitted N (Table 4). Available evidence indicates that molecular N accounts for 35% to 60% of the total N flux from biomass burning [e.g., *Kuhlbusch et al.*, 1991]; HCN, CH<sub>3</sub>CN, other nitriles, N<sub>2</sub>O, and higher-molecular weight organic gases are also emitted and thereby contribute to the observed imbalances between emitted N and corresponding sums of measured N-containing analytes.

[30] The relative contributions of species reported herein varied substantially among fuel types (Tables 2a-2d). For example, on the basis of median values of measured analytes, NO<sub>x</sub> was the most important N-containing species emitted during the combustion of grass, branches, agricultural waste, and charcoal; particulate N dominated emissions during combustion of litter; and NH<sub>3</sub> was the single most important species emitted during the combustion of dung.  $NH_4^+$  and  $NO_3^-$  generally accounted for less than half of total particulate N suggesting that organic N-containing species dominated particulate N emitted from most burns. As plumes age and cool, the composition and pH of particles evolve in response to the condensation of water and other primary emissions, the gas-phase production and subsequent condensation of acids, chemical reactions in bulk solutions and on surfaces, and phase partitioning of compounds with pH-dependent solubilities such as NH<sub>3</sub> and HNO<sub>3</sub> [e.g., Gao et al., 2003; Li et al., 2003; Magi and Hobbs, 2003]. Although generally lower relative to fluxes of other N-containing species, model calculations indicate that HONO significantly influences the cycling of HO<sub>X</sub> and O<sub>3</sub> in aging biomass-burning plumes [Trentmann et al., 2005].

[31]  $EF_{st}s$  for NO<sub>X</sub> for these experimental burns were generally within the range of values reported by *Andreae* and *Merlet* [2001] but those for NH<sub>3</sub> emitted during the combustion of savanna grasses were lower by an order of magnitude or more (Table 3). However,  $EF_{st}s$  for NH<sub>3</sub>

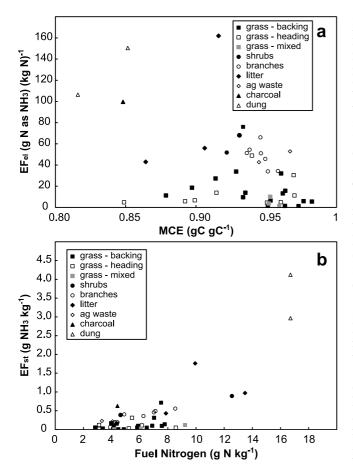

Figure 5. (a)  $EF_{el}$  for NH<sub>3</sub> versus MCE and (b)  $EF_{st}$  for NH<sub>3</sub> versus the N content of fuel.

during our grass burns fell within the lower end of the range of EF<sub>st</sub>s based on measurements in ambient plumes from savanna fires in southern Africa during SAFARI 2000  $(0.28 \pm 0.14 \text{ g/kg} \text{ [Yokelson et al., 2003]})$  and were similar to EF<sub>st</sub> for NH<sub>3</sub> reported for a savanna fire in Ivory Coast [Delmas et al., 1995]. To evaluate these data further, we compared EF<sub>el</sub>s for NH<sub>3</sub> measured during this study with results from a previous set of experimental burns of African savanna grasses and agricultural waste at the same facility [Lobert et al., 1990]. The average  $\text{EF}_{el}$  for all burns during the previous study (40 ± 31 g kg<sup>-1</sup>, N = 15) encompasses the range of average values for savanna grasses (15 ± 17 g kg<sup>-1</sup>, N = 28) and agricultural waste (48 g kg<sup>-1</sup>) N =2) measured during our experiments. We conclude that NH<sub>3</sub> emissions from savanna fires in southern Africa are quite variable and generally lower that those associated with other extratropical fires. Variability in the moisture and N contents of fuels, burn conditions, and perhaps volatilization from soils and subsurface roots upon heating by ambient fires contribute to the wide range in reported values.

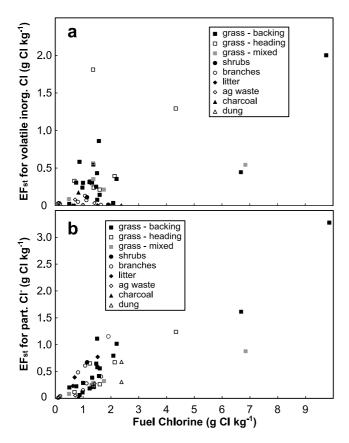

[32] Most NH<sub>3</sub> is emitted during the smoldering stage of fires [*Griffith et al.*, 1991; *Lobert et al.*, 1991] and, consequently, as for CH<sub>3</sub>COOH, we would expect an inverse relationship between  $EF_{el}$  and MCE. Fuels associated with relatively lower MCEs (dung, charcoal, and litter) exhibited generally higher  $EF_{els}$  and those for branches were significantly correlated (Figure 5a). In contrast,  $EF_{els}$ 

for grass fires did not exhibit a consistent pattern. The three highest EFels for individual grass fires were associated with MCEs around 0.93 but two other grass fires with similar MCEs exhibited substantially lower EF<sub>el</sub>s (Figure 5a). Most EF<sub>el</sub>s for NH<sub>3</sub> that corresponded to MCEs greater than 0.95 were relatively low and those associated with MCEs less than 0.92 decreased with decreasing MCE (Figure 5a). EF<sub>els</sub> for heading fires tended to be less than those for backing fires of similar MCE. Standard emission factors for NH<sub>3</sub> corresponding to ambient savanna fires during SAFARI 2000 were also poorly correlated with MCE [Yokelson et al., 2003]. Fuels with the highest N contents (dung, litter, and one shrub sample) exhibited systematically higher EF<sub>st</sub>s relative to other fuels (Figure 5b). With the exception of those for branches, however, the poor correlations between EF<sub>st</sub>s and the corresponding N contents of these other fuels (Figure 5b) indicate that N content had a minor to negligible influence on the corresponding NH<sub>3</sub> emissions during combustion.

[33] In India where dung is widely burned as fuel, the substantial associated NH<sub>3</sub> emissions (Tables 2a–2d and Figure 5b) have potentially important implications for the multiphase chemical processes. For example, enhanced titration of atmospheric acidity relative to other regions should result in higher aerosol pHs, which could sustain efficient S(IV) oxidation in aerosol solutions but quench halogen activation chemistry [e.g., *Keene et al.*, 1998]. In addition, high NH<sub>3</sub> mixing ratios may enhance aerosol nucleation [e.g., *Korhonen et al.*, 1999; *Kulmala et al.*, 2000] and efficient atmospheric deposition would contribute to eutrophication of ecosystems [e.g., *Russell et al.*, 2003]. Additional research is needed to critically evaluate the environmental implications of large NH<sub>3</sub> emissions from dung burning in India.

## 3.4. Halogens

[34] Compared to C and N, the Cl and Br contents of vegetation were more variable and relatively smaller fractions were emitted during combustion (median for all fuels = 73% for both Cl and Br, Table 1). Similar amounts of gaseous inorganic Cl and particulate Cl<sup>-</sup> were emitted during the combustion of savanna grass (Tables 2a-2d). With the exception of charcoal and shrubs, however, particulate Cl<sup>-</sup> was the primary Cl-containing analyte measured in the exhaust from combustion of other fuel types (Tables 2a-2d). Particulate Br<sup>-</sup> typically dominated inorganic Br emissions from all fuel types (Tables 2a-2d). EF<sub>st</sub>s for volatile inorganic and particulate halogens associated with most fuel types generally increased with increasing halogen content of biomass (Figure 6). These relationships illustrate that fuel composition partially controls the corresponding pyrogenic emissions of inorganic halogens. The greater scatter in the EF<sub>st</sub> versus fuel Cl for volatile inorganic Cl (Figure 6a) compared to that for particulate Cl<sup>-</sup> (Figure 6b) suggests that other factors including type of fuel are relatively more important in regulating emissions of volatile inorganic Cl. We infer from these results that regional variability in the halogen contents of fuels (e.g., relatively high in grasses of Etosha and relatively low branches of Malawi, Table 1) would contribute to systematic regional variability in the corresponding emissions from biomass

**Figure 6.**  $EF_{st}$  for (a) volatile inorganic Cl and (b) particulate Cl<sup>-</sup> versus the Cl content of fuel. Figure 6a excludes one litter sample with a high fuel Cl content of 19.4 g Cl kg<sup>-1</sup> and a corresponding  $EF_{st}$  for volatile inorganic Cl of 0.05 g Cl kg<sup>-1</sup>.

burning and associated influences on the chemical processing of plumes. On the basis of median values for all fires, inorganic gases and particulate ions accounted for 53% of the emitted Cl and 30% of the emitted Br (Table 4). Organic Cl- and Br-containing gases and particulate species composed the balance of total Cl and Br emitted during the experimental burns.

[35] The role of reactive inorganic halogens in the chemical evolution of biomass burning plumes is poorly constrained. On the basis of median values, HCl accounted for about half of total volatile inorganic Cl in fresh exhaust (Tables 2a-2d), which suggests that other, more reactive inorganic Cl gases such as Cl<sub>2</sub>, HOCl, and BrCl were emitted in significant concentrations. Rapid photolysis of these compounds in sunlight generates atomic Cl, which subsequently reacts rapidly with hydrocarbons (primarily alkanes) via H abstraction to produce HCl [e.g., Graedel and Keene, 1995]. At high HCl mixing ratios (>1 ppbv), the gas-phase reaction of HCl and OH also contributes significantly to Cl-atom production [e.g., Singh and Kasting, 1988]. At high NO<sub>X</sub>, the enhanced supply of odd hydrogen radicals from hydrocarbon oxidation by Cl contributes to O<sub>3</sub> production [e.g., Tanaka et al., 2000]. On the basis of its thermodynamic properties, HCl partitions with aqueous aerosols as a function of pH. In acidic solution, reaction of HOCl and HOBr with Cl<sup>-</sup> produces Cl<sub>2</sub> and BrCl, respectively, that subsequently volatilize and photolyze [e.g., *Sander* et al., 2003]. These multiphase pathways (e.g., HCl  $\rightarrow$  Cl<sup>-</sup>  $\rightarrow$  Cl<sub>2</sub>  $\rightarrow$  Cl  $\rightarrow$  HCl) recycle the relatively less reactive product species (HCl and particulate Cl<sup>-</sup>) to photochemically active forms. Because Cl atoms react with hydrocarbons primarily via H abstraction to produce HCl, such recycling would be required to sustain significant Cl-radical chemistry in aging plumes.

[36] The potential importance of oxidation by atomic Cl was evaluated in a biomass-burning plume during SAFARI 2000 on the basis of concentration changes in  $C_2H_2$  relative to CO, a conservative tracer [Tabazadeh et al., 2004]. Because C<sub>2</sub>H<sub>2</sub> is oxidized rapidly by atomic Cl but not by OH, decreasing ratios of  $\Delta C_2 H_2 / \Delta CO$  with time would indicate significant Cl-atom concentrations. However, ratios based on measurements over a period of about 1 hour following emission were relatively constant indicating negligible oxidation by atomic Cl. Our results indicate that volatile inorganic Cl and particulate Clwere present at high concentrations in plumes from savanna fires in this region. In addition, emission ratios for major acids (CH<sub>3</sub>COOH, HCOOH and HCl) and acid precursors (SO<sub>2</sub>, NO<sub>X</sub>, volatile inorganic Cl other than HCl) exceeded those for NH<sub>3</sub> in all fires suggesting that condensed solutions in evolving plumes were either acidic or rapidly acidified. However, the low ambient relative humidity (RH,  $\sim 40\%$ ) and associated liquid water may have limited multiphase recycling leading to the accumulation of relatively unreactive HCl and particulate Cland thus little Cl-atom production in the aging plume. High concentrations of condensed organics on surfaces and in bulk solution may have also influenced HCl phase partitioning and corresponding rates of Cl recycling. At higher RH and associated liquid water (e.g., exhaust from temperate wildfires), Cl-radical chemistry may be relatively more important in the chemical evolution of plumes.

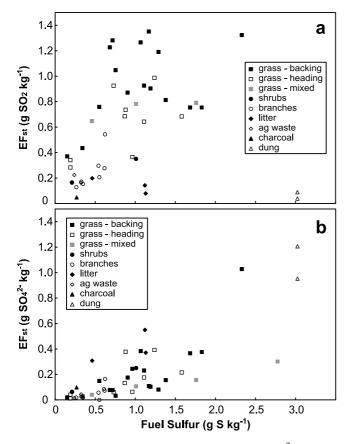

[37] The measured emission fluxes of gaseous, inorganic Br and particulate Br<sup>-</sup> in association with acids and particles suggests that Br radicals may also influence the chemical evolution of biomass-burning plumes. Analogous multiphase pathways involving sea-salt aerosol impact the cycling of NO<sub>X</sub>, O<sub>3</sub>, S, and other constituents of marine air [e.g., *Sander et al.*, 2003; *Pszenny et al.*, 2004, and references therein]. On the basis of the measured speciation of volatile inorganic Cl, we hypothesize that a significant fraction of volatile inorganic Br was emitted in photochemically active forms including Br<sub>2</sub>, BrCl, and HOBr. Photolysis of these compounds generates atomic Br that catalytically destroys ozone via:

$$Br + O_3 \rightarrow BrO + O_2$$
 (1)

$$BrO + HO_2 \rightarrow HOBr + O_2$$
 (2)

$$HOBr + h\nu \rightarrow OH + Br$$
 (3)

Because biomass-burning plumes also contain high concentrations of HCHO and other oxygenated organic

**Figure 7.**  $EF_{st}$  for (a) SO<sub>2</sub> and (b) particulate SO<sub>4</sub><sup>2-</sup> versus the S content of fuel.

compounds [e.g., Yokelson et al., 2003], important side reactions such as

$$Br + HCHO + O_2 \rightarrow HBr + CO + HO_2$$
 (4)

may limit gas-phase recycling of Br radicals [e.g., *Dickerson et al.*, 1999] and lead to accumulation of particulate Br<sup>-</sup> via condensation of HBr. Like Cl, activation of particulate Br<sup>-</sup>, which dominated inorganic Br emissions during the experimental burns (Tables 2a-2d), requires aqueous media. As may be the case for inorganic Cl, the low RHs and associated liquid water perhaps coupled with the high concentrations of condensed organic compounds may limit active Br-radical chemistry in biomass-burning exhaust over southern Africa. Focused experiments over a wider range of RH are needed to resolve the potentially important influences of halogen radicals in the chemical evolution of biomass-burning plumes.

#### 3.5. Sulfur

[38] The S contents of vegetation varied significantly across the region with highest values in Etosha and lowest in the Miombo woodlands (Table 1). On the basis of median values for all burns, 76% of this S was emitted (Table 1) and 51% of the emitted S was in form of SO<sub>2</sub> and particulate SO<sub>4</sub><sup>2–</sup> (Table 4). Presumably, the balance was composed primarily of H<sub>2</sub>S, COS, other organic S-containing gases, and particulate species. Like inorganic Cl, inorganic S emissions were correlated with S contents (Figure 7) and the relative impor-

tance of gaseous versus particulate emissions varied substantially as a function of fuel type (Tables 2a-2d). SO<sub>2</sub> typically dominated inorganic S emissions during the combustion of grass, branches, and agricultural wastes whereas particulate S was the major inorganic S species emitted during the combustion of litter and dung. The low EFsts for SO2 and particulate  $SO_4^{2-}$  from charcoal fires (Tables 2a-2d) reflects the relatively low S content of the fuel (Table 1). Heterogeneity in S content of the charcoal sample (as inferred from large variability in S associated with ash from replicate burns) precluded reliable quantification of corresponding EF<sub>el</sub>s. Median EF<sub>st</sub>s for SO<sub>2</sub> during the combustion of most fuel types evaluated during this study were within a factor of two of the corresponding values recommended by Andreae and Merlet [2001]; the EF<sub>st</sub> for charcoal based on our results was a factor of 8 lower (Table 3).

## 3.6. Phosphorous

[39] The P contents of vegetation varied substantially among the same fuel type within a given region (e.g., factor of 8 among grasses in Etosha), between different fuel types in the same region (e.g., branches were generally factors of 2 to 10 lower than grasses), and between the same fuel type in different regions (e.g., grasses of the Miombo Dambos were about a factor of 10 lower than most of those in other regions, Table 1). Like those for N, the low P contents of Miombo grasses reflects the relative infertility of these ecosystems [e.g., Hély et al., 2003]. On the basis of median values for all burns, 82% of the P was emitted during combustion but only 0.1% was recovered in the form of particulate  $PO_4^{3-}$ . These results suggest that most P in biomass is emitted during combustion in association with organic, probably particulate species. To our knowledge, a satisfactory chemical mass balance for P during biomass burning does not exist. However, results from this investigation imply substantial mobilization associated with large net losses of P from burned ecosystems and potentially important exogenous sources of nutrient P for downwind ecosystems. To resolve the potential importance of this large biogeochemical flux, experiments should be conducted to determine the total P content of emitted particles and its associated bioavailability.

#### 3.7. Base Cations

[40] The base cation contents of fuels varied substantially among regions (those in Etosha were relatively high and in Zambia relatively low) and fuel types (e.g., shrubs were more concentrated in K and branches in Ca; Table 1). On the basis of median values, most K, Ca, Na, and Mg (66%, 74%, 78%, and 84%, respectively) were emitted during combustion (Table 1). However, only minor fractions were recovered as soluble particulate K<sup>+</sup>, Ca<sup>2+</sup>, Na<sup>+</sup>, and Mg<sup>2+</sup> (median values of 11%, 0.8%, 3.8%, and 1.0%, respectively, Table 4). On the basis of these results, we infer that most base cations in fuels were emitted during combustion in association with insoluble particulate compounds. EF<sub>st</sub>s for K<sup>+</sup> were within the range previously published values (Table 3).

# 4. Conclusions

[41] 1. The middle 50th percentile range of MCEs for all burns (0.91 to 0.95 g C g  $C^{-1}$ ) was similar to the reported

range for ambient savanna fires in southern Africa. Lower MCEs were generally associated with higher moisture contents, heading versus backing fires, and processed fuels (dung, charcoal).

[42] 2. Virtually all (median = 97%) fuel C was emitted during combustion primarily as  $CO_2$  and CO (median = 99%). EF<sub>el</sub> for CH<sub>3</sub>COOH was negatively correlated with MCE; during the combustion of savanna grasses, most heading and mixed fires exhibited systematically higher EF<sub>el</sub>s for CH<sub>3</sub>COOH relative to backing fires of comparable MCEs.

[43] 3. Measured analytes in the exhaust (NO<sub>X</sub>, NH<sub>3</sub>, HONO, and particulate N) accounted for relatively minor fractions of the emitted N (median = 22%); on the basis of *Kuhlbusch et al.* [1991], we infer that N<sub>2</sub> contributed most of the unmeasured balance. Significant HONO but virtually no HNO<sub>3</sub> were emitted during the experimental burns. Savanna grass fires with the highest  $EF_{els}$  for NH<sub>3</sub> were associated with MCEs around 0.93; fires with higher and lower MCEs exhibited lower  $EF_{els}$ . Fuels with the highest N contents (dung and litter) exhibited the highest  $EF_{st}$ s for NH<sub>3</sub>. With the exception of branch fires, however, NH<sub>3</sub> emissions during combustion of other fuels were poorly correlated with the N content.

[44] 4. Most Cl and Br in fuel (median for both = 73%) was emitted during the experimental burns. On the basis of median values, volatile inorganic species and particulate ions accounted for 53% of emitted Cl and 30% of the emitted Br. HCl accounted for about half of volatile inorganic Cl suggesting that other, more reactive, species (including Cl<sub>2</sub>, HOCl, BrCl) were also emitted in significant concentrations. The halogen contents of fuels partially regulated corresponding pyrogenic emissions.

[45] 5. On the basis of median values for all burns, 76% of fuel S was emitted during combustion and 51% of the emitted S was in form of SO<sub>2</sub> and particulate  $SO_4^{2-}$ .

[46] 6. On the basis of median values for all burns, 82% of fuel P was emitted during combustion but only 0.1% was recovered in the form of particulate  $PO_4^{3-}$ . These results imply large net losses of P from burned ecosystems and potentially important exogenous sources of nutrient P for downwind ecosystems.

[47] 7. On the basis of median values, most K, Ca, Na, and Mg in fuel (66%, 74%, 78%, and 84%, respectively) was emitted during combustion but little (11%, 0.8%, 3.8%, and 1.0%, respectively) was recovered as soluble particulate  $K^+$ ,  $Ca^{2+}$ ,  $Na^+$ , and  $Mg^{2+}$ .

[48] Acknowledgments. We thank P. Desanker, M. Garstang, M. Kaiser, H. Shugart, and R. Swap at the University of Virginia; H. Annegarn at the University of Witwatersrand; D. Kayambazinthu at the Forestry Research Institute of Malawi; and staff at Etosha National Park for assistance in securing vegetation samples from southern Africa. J. Lelieveld, J. Williams, and staff at the Max Plank Institute for Chemistry provided facilities and technical support for the experimental burns. H. Friedli, J. Trentmann, and an anonymous reviewer offered helpful comments; C. Jenkins assisted with sample analysis. The National Science Foundation provided financial support through award ATM 0003865 to the University of Virginia and award ATM 001424 to the University of California, San Diego. This work is part of the Southern African Regional Science Initiative–SAFARI 2000.
